## ABSTRACT

The modeling of the diffusion MRI signal from moving and deforming organs such as the heart is challenging due to significant motion and deformation of the imaged medium during the signal acquisition. Recently, a mathematical formulation of the Bloch-Torrey equation, describing the complex transverse magnetization due to diffusion-encoding magnetic field gradients, was developed to account for the motion and deformation. In that work, the motivation was to cancel the effect of the motion and deformation in the MRI image and the space scale of interest spans multiple voxels. In the present work, we adapt the mathematical equation to study the diffusion MRI signal at the much smaller scale of biological cells.

We start with the Bloch-Torrey equation defined on a cell that is moving and deforming and linearize the equation around the magnitude of the diffusion-encoding gradient. The result is a second order signal model in which the linear term gives the imaginary part of the diffusion MRI signal and the quadratic term gives the apparent diffusion coefficient (ADC) attributable to the biological cell. We numerically validate this model for a variety of motions and deformations.

## 1. Introduction

Diffusion MRI is an imaging modality that is capable of generating images with a contrast that is sensitive to the diffusional motion of water molecules [1]. It plays a very important role in the study of the microscopic structure of biological tissues by measuring the diffusion characteristics of water molecules averaged at the scale of the imaging voxel. While this technique has been very successfully applied to static organs such as the brain [2–4], the interpretation of the diffusion MRI signal from moving organs like the beating heart is made difficult by the tissue motion and deformation during acquisition. In healthy hearts, the long axes of cardiac myocytes are orientated in a helical arrangement through the ventricular wall and the cardiac cells are organized in laterally reinforced layers (sheetlets) of a few cells in thickness [5,6]. Cardiac diffusion MRI can be used to show angular differences in hypertrophic cardiac myopathy which could be fundamental in assessing heart disease [7–9]. The sensitivity of diffusion MRI to cardiac motion makes it difficult to assess to what extent the

diffusion measurements reflect the real properties of the cardiac tissues. This is illustrated in some experimental studies introduced, for example, in [10–15].

The signal measured in diffusion MRI is the total transverse magnetization in a voxel. This magnetization can be modeled by the complex-valued Bloch-Torrey partial differential equation (PDE) [16]. Originally, this equation was proposed to explain the signal attenuation due to diffusion at the scale of the image, with an (apparent) diffusion coefficient assigned to each voxel. More recently, it has been used to model the transverse magnetization at the microscopic scale, on the scale of the individual cells. In this way, one can study the contribution to the signal that is attributable to various types of cells or to the extra-cellular space inside the imaging voxel. In static organs, such as the brain, modeling and simulation efforts that link the measured diffusion MRI signal with the geometric structure of the cells and the extra-cellular space include analytical works (see, for example, [17,18]) and numerical works (see, for example [19–25]). For the heart, we cite the works [26–30] in which *ex-vivo* diffusion MRI is presented by performing numerical simulations on a model of fiber phantom and virtual cardiac microstructure. This model includes a simplified representation of individual cells, with physiologically correct cell size and orientation, and the diffusion MRI is simulated using a Monte Carlo

method and realistic MRI sequences. The results are then compared with experimental measurements to validate the proposed model.

In contrast to the vast amount of past works for static organs, very few previous modeling and simulation works exist that include the influence of significant physiological motion of the imaged organ during the diffusion MRI acquisition. In [31] the Bloch-Torrey equation is expressed in generalized curvilinear coordinates to describe the behavior of the magnetization in the heart during its deformation over the cardiac cycle and a change of basis formula was used in order to take into account the effect of motion on diffusion. In another recent work [32], a mathematical formulation of the Bloch-Torrey PDE was developed to account for the motion and deformation. That formulation was obtained by writing the Bloch-Torrey PDE in a domain that deforms over time according to the laws of continuum mechanics and the interest was on cancelling the effect of the motion in the MRI images. In the present work, we adapt the mathematical equations developed in [32] to study the diffusion MRI signal arising from cells, i.e., the scale of interest will be much smaller than that of the imaging voxel.

In Section 2 we introduce the Bloch-Torrey equation in a moving and deforming biological cell at the microscopic scale. Section 3 is dedicated to the derivation of a new second order model using linearization technique on the solution of the Bloch-Torrey equation. In the new model, the linear term gives the imaginary part of the diffusion MRI signal and the quadratic term gives the ADC attributable to the biological cell. In Section 4, we present some numerical simulations to validate our model in the presence of an analytical deformation for different geometries of the biological cell. We conclude with some remarks in Section 5.

## 2. Theory

Let  $\Omega \subset \mathbb{R}^{dim}$  be the interior of a biological cell ( $dim$  being the space dimension), and let  $\Gamma = \partial\Omega$  be its boundary. In what follows, we will make the simplifying assumption that the cell membrane is impermeable. We first describe the Bloch-Torrey PDE in a static cell and then in a moving and deforming cell.

### 2.1. Bloch-Torrey PDE in a biological cell

The complex-valued transverse water proton magnetization  $M$  in  $\Omega$  can be described by the following Bloch-Torrey PDE[16]:

$$\begin{cases} \partial_t M(\mathbf{x}, t) - \operatorname{div}_{\mathbf{x}}(\sigma \nabla_{\mathbf{x}} M(\mathbf{x}, t)) + i\gamma \mathbf{g} \cdot \mathbf{x} f(t) M(\mathbf{x}, t) = 0 & \text{in } \Omega \times (0, T) \\ \sigma \nabla M \cdot \mathbf{n}_{\mathbf{x}} = 0 & \text{on } \Gamma \times (0, T) \\ M(\mathbf{x}, 0) = \rho & \text{on } \Omega \times \{0\} \end{cases} \quad (1)$$

where  $\mathbf{n}_{\mathbf{x}}$  is the outward pointing normal to  $\Omega$ ,  $\rho$  is the initial magnetization. The coefficient  $\sigma$  is the intrinsic diffusion coefficient and is assumed constant in  $\Omega$ ,  $\gamma = 2.67513 \times 10^8 \text{ rad s}^{-1} \text{ T}^{-1}$  is the gyromagnetic ratio of the water proton, and the vector  $\mathbf{g} = g\mathbf{u}_{\mathbf{g}}$  is the applied diffusion-encoding magnetic field gradient ( $g$  containing its magnitude,  $\mathbf{u}_{\mathbf{g}}$  is a unit direction vector in  $\mathbb{R}^{dim}$ ). The function  $f$  is a normalized time profile of the diffusion-encoding magnetic field gradient sequence. The time profile of the standard Pulsed Gradient Spin Echo (PGSE) [17] sequence, simplified to include only the parameters relevant to diffusion, is:

$$f(t) = \begin{cases} 1 & \text{if } 0 < t \leq \delta, \\ -1 & \text{if } \Delta < t \leq \Delta + \delta, \\ 0 & \text{elsewhere.} \end{cases} \quad (2)$$

The time at which the signal is measured is called the echo time  $TE \geq \Delta + \delta$ . The logarithm of the diffusion MRI signal is usually plotted against the b-value:

$$b := \gamma^2 \|\mathbf{g}\|^2 \int_0^{TE} F(t)^2 dt = \gamma^2 \|\mathbf{g}\|^2 \delta^2 \left( \Delta - \frac{\delta}{3} \right),$$

where

$$F(t) = \int_0^t f(s) ds.$$

The b-value is an important quantity in diffusion MRI. Typically, for different choices of  $\Delta$  and  $\delta$ , the value of  $\|\mathbf{g}\|$  is adjusted so that the same set of b-values is used.

While physically, the measurable diffusion MRI signal is due to the spins in all the biological cells and the extra-cellular space in a voxel, it makes mathematical sense to define the part of the diffusion MRI signal due to a particular biological cell in order to isolate and study its diffusion characteristics. We define the diffusion MRI signal from the cell  $\Omega$  as the integral of the magnetization at  $TE$  over  $\Omega$ :

$$S = \int_{\Omega} M(\mathbf{x}, TE) d\mathbf{x}.$$

It then follows that the effective diffusion coefficient of the biological cell  $\Omega$  can be defined as:

$$D_{\mathbf{u}_{\mathbf{g}}}^{\text{eff}} \equiv - \frac{1}{\gamma^2 \int_0^{TE} F(t)^2 dt} \frac{\partial}{\partial g^2} \ln \left( \frac{S}{S_0} \right) \Bigg|_{g=0}, \quad (3)$$

where  $S_0$  is the integral of the magnetization over  $\Omega$ , measured for  $g = 0$ . The  $D_{\mathbf{u}_{\mathbf{g}}}^{\text{eff}}$  defined in the formula in Eq. (3) depends on the gradient direction  $\mathbf{u}_{\mathbf{g}}$  and the temporal profile  $f(t)$ , but not on the gradient amplitude  $g$ .

In the MRI community, the effective diffusion coefficient is fitted using the measured diffusion MRI signal at several b-values and the value is referred to as the "apparent diffusion coefficient" (ADC). The ADC is widely used in medical applications, for instance, ADC maps of brain have been used to identify tumors (see [33]).

### 2.2. Moving and deforming biological cell

We consider a moving and deforming biological cell  $\Omega(t) \subset \mathbb{R}^{dim}$  on the time interval  $t \in [0, T]$  with  $T > 0$ . Let us introduce the geometric transformation  $\varphi$  which is a differentiable, time-space dependent function:

$$\begin{aligned} \varphi : (0, T) \times \Omega(0) &\rightarrow \Omega(t), \\ (t, \mathbf{x}) &\mapsto \varphi(t, \mathbf{x}) = X, \end{aligned}$$

and assume that at each point  $\mathbf{x}$ , the curve  $t \mapsto \varphi(t, \mathbf{x})$  satisfies:

$$\begin{aligned} \partial_t \varphi(t, \mathbf{x}) &= \mathbf{v}(\varphi(t, \mathbf{x}), t), \\ \varphi(0, \mathbf{x}) &= \mathbf{x}, \end{aligned}$$

where  $\mathbf{v}$  is the velocity field  $\mathbf{v} : \mathbb{R}^{dim} \rightarrow \mathbb{R}^{dim}$ . In short, the moving and deforming domain  $\{\Omega(t)\}_{t \in [0, T]}$  evolves from the initial domain  $\Omega(0) \subset \mathbb{R}^{dim}$  according to the transformation  $\varphi$ .

The time variation of the magnetization  $M$  in  $\Omega(t)$  can be written as a function of the diffusion flux through the boundary  $\Gamma(t)$ :

$$\frac{d}{dt} \int_{\Omega(t)} M(X, t) dX = \int_{\Gamma(t)} \sigma \nabla_X M(X, t) \cdot \mathbf{n}_X dS_X.$$

By using the Reynolds transport theorem [34] and taking into account the frequency term ( $i\gamma \mathbf{g} \cdot \mathbf{x} f(t) M(\mathbf{x}, t)$ ) in the Bloch-Torrey PDE in a static domain, we recover the Bloch-Torrey PDE in the moving domain as:

$$\begin{cases} \partial_t M(X, t) - \operatorname{div}_X(\sigma \nabla_X M(X, t)) + \operatorname{div}_X(M(X, t) \mathbf{v}(X, t)) \\ + i\gamma \mathbf{g} \cdot X f(t) M(X, t) = 0 \\ \text{in } \Omega(t) \times (0, T) \\ \sigma \nabla M \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma(t) \times (0, T) \\ M(X, 0) = \rho(X) \quad \text{on } \Omega(t) \times \{0\}. \end{cases} \quad (4)$$

To transform the magnetization  $M$ , defined on the deforming domain to a related quantity  $\bar{M}$  on the initial domain, we use the definition:

$$\begin{aligned} \bar{M} : \Omega(0) \times (0, T) &\rightarrow \mathbb{R} \\ \bar{M}(\mathbf{x}, t) &\mapsto M(\boldsymbol{\varphi}(t, \mathbf{x}), t). \end{aligned}$$

From [32], under the assumption of the incompressibility of the medium:

$$\operatorname{div}_X(\mathbf{v}) = 0, \quad \det(\mathbf{J}_\varphi) = 1,$$

the Bloch-Torrey PDE for  $\bar{M}$  on  $\Omega(0)$  can be written as:

$$\begin{cases} \partial_t \bar{M}(\mathbf{x}, t) - \operatorname{div}(\mathbf{J}_\varphi^{-1} \sigma \mathbf{J}_\varphi^T \nabla \bar{M}(\mathbf{x}, t)) \\ + i\gamma \mathbf{g} \cdot \boldsymbol{\varphi}(t, \mathbf{x}) f(t) \bar{M}(\mathbf{x}, t) = 0 \text{ in } \Omega(0) \times (0, T), \\ \mathbf{J}_\varphi^{-1} \sigma \mathbf{J}_\varphi^T \nabla \bar{M} \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma(0) \times (0, T), \\ \bar{M}(\mathbf{x}, 0) = \rho(\mathbf{x}) \quad \text{on } \Omega(0) \times \{0\}, \end{cases} \quad (5)$$

where  $\mathbf{J}_\varphi = \nabla_X \boldsymbol{\varphi}$  is the Jacobian matrix of the deformation field  $\boldsymbol{\varphi}$ . We use the notation:

$$\mathbf{J}_\varphi^{-T} \equiv (\mathbf{J}_\varphi^{-1})^T.$$

The vector  $\mathbf{n}_X$  is the outward pointing normal to  $\Omega(0)$ .

In this paper we consider Eq. (5) as the reference model and we refer to it as BTPDE-D (for Bloch-Torrey PDE in a deforming domain), from which we will derive, in the next section, the ADC of a moving and deforming cell. The diffusion MRI signal, obtained by solving Eq. (5), will be called the reference signal:

$$S_{ref} = \int_{\Omega} \bar{M}(\mathbf{x}, TE) d\mathbf{x}. \quad (6)$$

For the details on the derivation of BTPDE-D, the reader is referred to [32].

### 3. ADC of BTPDE-D using linearization

In this section we derive the ADC of BTPDE-D using linearization around  $\mathbf{g}$ , the magnitude of the diffusion-encoding gradient in (5).

Let us decompose the deformation field as:

$$\boldsymbol{\varphi}(t, \mathbf{x}) := \mathbf{x} + \mathbf{d}(t, \mathbf{x}),$$

where  $\mathbf{d}$  is a displacement field, and we define the Jacobian matrix of  $\boldsymbol{\varphi}$  by:

$$\mathbf{J}_\varphi := \mathbf{I} + \mathbf{J}_d,$$

with  $\mathbf{J}_d = \nabla_X \mathbf{d}$  being the Jacobian matrix of  $\mathbf{d}$ .

We transform the magnetization  $\bar{M}$  (5) by defining a new unknown  $\tilde{M}$ :

$$\bar{M}(\mathbf{x}, t) = \tilde{M}(\mathbf{x}, t) \exp\left(-i\gamma \mathbf{g} \cdot \mathbf{x} \int_0^t f(s) ds\right).$$

It is easy to show that  $\tilde{M}$  satisfies the following problem:

$$\begin{cases} \partial_t \tilde{M}(\mathbf{x}, t) - \operatorname{div}(\mathbf{K}(\nabla \tilde{M}(\mathbf{x}, t) - i\gamma \mathbf{g} F(t) \tilde{M}(\mathbf{x}, t)) + iF(t) \mathbf{K} \gamma \mathbf{g} \cdot \nabla \tilde{M}(\mathbf{x}, t), \\ + [\mathbf{K} \gamma \mathbf{g} \cdot \gamma \mathbf{g} F^2(t) + i\gamma \mathbf{g} \cdot \mathbf{d}(t, \mathbf{x}) f(t)] \tilde{M}(\mathbf{x}, t) = 0 \text{ in } \Omega \times (0, T), \\ \mathbf{K}[\nabla \tilde{M} - i\gamma \mathbf{g} F(t) \tilde{M}] \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma \times (0, T), \\ \tilde{M}(\mathbf{x}, 0) = \rho \quad \text{on } \Omega \times \{0\}. \end{cases} \quad (7)$$

where

$$\mathbf{K} = \mathbf{J}_\varphi^{-1} \sigma \mathbf{J}_\varphi^{-T}.$$

Under the assumption that the initial magnetization  $\rho$  is constant, we introduce a non-dimensional parameter  $\varepsilon > 0$  in  $\mathbf{g}$ , so that  $\mathbf{g} = \varepsilon \tilde{\mathbf{g}}$ . Then (7) becomes:

$$\begin{cases} \partial_t \tilde{M}_\varepsilon(\mathbf{x}, t) - \operatorname{div}(\mathbf{K}(\nabla \tilde{M}_\varepsilon(\mathbf{x}, t) - i\varepsilon \gamma \tilde{\mathbf{g}} F(t) \tilde{M}_\varepsilon(\mathbf{x}, t)) + i\varepsilon F(t) \mathbf{K} \gamma \tilde{\mathbf{g}} \cdot \nabla \tilde{M}_\varepsilon(\mathbf{x}, t), \\ + [\varepsilon^2 \mathbf{K} \gamma \tilde{\mathbf{g}} \cdot \gamma \tilde{\mathbf{g}} F^2(t) + i\varepsilon \gamma \tilde{\mathbf{g}} \cdot \mathbf{d}(t, \mathbf{x}) f(t)] \tilde{M}_\varepsilon(\mathbf{x}, t) = 0 \text{ in } \Omega \times (0, T), \\ \mathbf{K}[\nabla \tilde{M}_\varepsilon - i\varepsilon \gamma \tilde{\mathbf{g}} F(t) \tilde{M}_\varepsilon] \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma \times (0, T), \\ \tilde{M}_\varepsilon(\mathbf{x}, 0) = \rho \quad \text{on } \Omega \times \{0\}, \end{cases} \quad (8)$$

Assuming  $\varepsilon$  is small, we write  $\tilde{M}_\varepsilon(\mathbf{x}, t)$  as an expansion in powers of  $\varepsilon$ :

$$\tilde{M}_\varepsilon(\mathbf{x}, t) = \sum_{j=0}^{\infty} \varepsilon^j \tilde{M}_j(\mathbf{x}, t).$$

Inserting the above expansion in (8), we recover the following equations for the first three terms.

- For  $\tilde{M}_0$  :

$$\begin{cases} \partial_t \tilde{M}_0(\mathbf{x}, t) - \operatorname{div}(\mathbf{K} \nabla \tilde{M}_0(\mathbf{x}, t)) = 0 \text{ in } \Omega \times (0, T) \\ \mathbf{K} \nabla \tilde{M}_0 \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma \times (0, T) \\ \tilde{M}_0(\mathbf{x}, 0) = \rho \quad \text{on } \Omega \times \{0\}. \end{cases} \quad (9)$$

- For  $\tilde{M}_1$  :

$$\begin{cases} \partial_t \tilde{M}_1(\mathbf{x}, t) - \operatorname{div}(\mathbf{K} \nabla \tilde{M}_1(\mathbf{x}, t)) + \operatorname{idiv}(\mathbf{K} \gamma \tilde{\mathbf{g}} F(t) \tilde{M}_0(\mathbf{x}, t)) \\ + iF(t) \mathbf{K} \gamma \tilde{\mathbf{g}} \cdot \nabla \tilde{M}_0(\mathbf{x}, t) + i\gamma \tilde{\mathbf{g}} \cdot \mathbf{d}(t, \mathbf{x}) f(t) \tilde{M}_0 = 0 \text{ in } \Omega \times (0, T) \\ \mathbf{K}[\nabla \tilde{M}_1 - i\gamma \tilde{\mathbf{g}} F(t) \tilde{M}_0] \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma \times (0, T) \\ \tilde{M}_1(\mathbf{x}, 0) = 0 \quad \text{on } \Omega \times \{0\}. \end{cases} \quad (10)$$

- For  $\tilde{M}_2$  :

$$\begin{cases} \partial_t \tilde{M}_2(\mathbf{x}, t) - \operatorname{div}(\mathbf{K}(\nabla \tilde{M}_2(\mathbf{x}, t) - i\gamma \tilde{\mathbf{g}} F(t) \tilde{M}_1(\mathbf{x}, t)) + iF(t) \mathbf{K} \gamma \tilde{\mathbf{g}} \cdot \nabla \tilde{M}_1(\mathbf{x}, t) + \mathbf{K} \gamma \tilde{\mathbf{g}} \cdot \gamma \tilde{\mathbf{g}} F^2(t) \rho \\ + i\gamma \tilde{\mathbf{g}} \cdot \mathbf{d}(t, \mathbf{x}) f(t) \tilde{M}_1 = 0 \text{ in } \Omega \times (0, T) \\ \mathbf{K}[\nabla \tilde{M}_2 - i\gamma \tilde{\mathbf{g}} F(t) \tilde{M}_1] \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma \times (0, T) \\ \tilde{M}_2(\mathbf{x}, 0) = 0 \quad \text{on } \Omega \times \{0\}. \end{cases} \quad (11)$$

From (9) we deduce that

$$\tilde{M}_0 \equiv \rho. \quad (12)$$

Consequently (10) is:

$$\begin{cases} \partial_t \tilde{M}_1(\mathbf{x}, t) - \operatorname{div}(\mathbf{K} \nabla \tilde{M}_1(\mathbf{x}, t)) + \operatorname{idiv}(\mathbf{K} \gamma \tilde{\mathbf{g}} F(t) \rho) \\ + i\gamma \tilde{\mathbf{g}} \cdot \mathbf{d}(t, \mathbf{x}) f(t) \rho = 0 \text{ in } \Omega \times (0, T) \\ \mathbf{K}[\nabla \tilde{M}_1 - i\gamma \tilde{\mathbf{g}} F(t) \rho] \cdot \mathbf{n}_X = 0 \quad \text{on } \Gamma \times (0, T) \\ \tilde{M}_1(\mathbf{x}, 0) = 0 \quad \text{on } \Omega \times \{0\}. \end{cases} \quad (13)$$

From (13) we observe that  $\tilde{M}_1$  is purely imaginary, and it can be written as:

$$\tilde{M}_1 = i\rho\gamma\|\tilde{\mathbf{g}}\|\omega(\mathbf{x}, t), \tag{14}$$

where  $\omega(\mathbf{x}, t)$  is the solution of:

$$\begin{cases} \partial_t \omega(\mathbf{x}, t) - \text{div}(\mathbf{K}\nabla\omega(\mathbf{x}, t) - F(t)\mathbf{K}\mathbf{u}_g) + \mathbf{u}_g \cdot \mathbf{d}(t, \mathbf{x})f(t) = 0 \text{ in } \Omega \times (0, T) \\ \mathbf{K}[\nabla\omega - F(t)\mathbf{u}_g] \cdot \mathbf{n}_x = 0 \text{ on } \Gamma \times (0, T) \\ \omega(\mathbf{x}, 0) = 0 \text{ on } \Omega \times \{0\}. \end{cases} \tag{15}$$

Equivalently, by defining  $\tilde{\omega}(\mathbf{x}, t) = \omega(\mathbf{x}, t) - F(t)\mathbf{u}_g \cdot \mathbf{x}$ , we get for  $\tilde{\omega}$ :

$$\begin{cases} \partial_t \tilde{\omega}(\mathbf{x}, t) - \text{div}(\mathbf{K}\nabla\tilde{\omega}(\mathbf{x}, t)) + \mathbf{u}_g \cdot (\mathbf{x} + \mathbf{d}(t, \mathbf{x}))f(t) = 0 \text{ in } \Omega \times (0, T) \\ \mathbf{K}[\nabla\tilde{\omega}] \cdot \mathbf{n}_x = 0 \text{ on } \Gamma \times (0, T) \\ \tilde{\omega}(\mathbf{x}, 0) = 0 \text{ on } \Omega \times \{0\}. \end{cases} \tag{16}$$

and

$$\tilde{M}_1 = i\rho\gamma\|\tilde{\mathbf{g}}\|(\tilde{\omega}(\mathbf{x}, t) + F(t)\mathbf{u}_g \cdot \mathbf{x}). \tag{17}$$

After integration in time and space of (11) we recover:

$$\begin{aligned} \int_{\Omega} \tilde{M}_2 + i \int_0^t F(s) \int_{\Omega} \mathbf{K}\gamma\tilde{\mathbf{g}} \cdot \nabla\tilde{M}_1(\mathbf{x}, s) + \rho \int_0^t F^2(s) \int_{\Omega} \mathbf{K}\gamma\tilde{\mathbf{g}} \cdot \gamma\tilde{\mathbf{g}} \\ + i \int_0^t f(s) \int_{\Omega} \gamma\tilde{\mathbf{g}} \cdot \mathbf{d}(s, \mathbf{x})\tilde{M}_1 = 0. \end{aligned} \tag{18}$$

By using the expression of the imaginary part of  $M_1$  (17), (18) becomes:

$$\begin{aligned} \int_{\Omega} \tilde{M}_2 = \rho \int_0^t F(s) \int_{\Omega} \mathbf{K}\gamma\tilde{\mathbf{g}} \cdot \nabla\omega(\mathbf{x}, s)\|\gamma\tilde{\mathbf{g}}\| - \rho \int_0^t F^2(s) \int_{\Omega} \mathbf{K}\gamma\tilde{\mathbf{g}} \cdot \gamma\tilde{\mathbf{g}} \\ + \rho \int_0^t f(s) \int_{\Omega} \gamma\tilde{\mathbf{g}} \cdot \mathbf{d}(s, \mathbf{x})\omega(\mathbf{x}, s)\|\gamma\tilde{\mathbf{g}}\|. \end{aligned} \tag{19}$$

The transverse magnetization of the biological cell  $\Omega$  to a second order approximation in  $\varepsilon$  is:

$$\tilde{M}_\varepsilon \approx \tilde{M}_0 + \varepsilon\tilde{M}_1 + \varepsilon^2\tilde{M}_2, \tag{20}$$

and the diffusion MRI signal is:

$$S_{new} = \int_{\Omega} (\rho + \varepsilon\tilde{M}_1(\mathbf{x}, TE) + \varepsilon^2\tilde{M}_2(\mathbf{x}, TE))d\mathbf{x}.$$

Inserting the expression into the original variable  $\mathbf{g}$  gives the approximation to the signal:

$$\frac{S_{new}}{\rho|\Omega|} = 1 + i\|\gamma\tilde{\mathbf{g}}\|S_{new}^{imag} - ADC_{new}\|\gamma\tilde{\mathbf{g}}\|^2 \int_0^{TE} F(t)^2 dt, \tag{21}$$

where the imaginary part of the signal accounts for the linear term in  $\gamma\tilde{\mathbf{g}}$ :

$$S_{new}^{imag} = \frac{1}{|\Omega|} \int_{\Omega} \omega(\mathbf{x}, TE)d\mathbf{x} = -\frac{1}{|\Omega|} \int_0^{TE} \int_{\Omega} \mathbf{u}_g \cdot \mathbf{d}(t, \mathbf{x})d\mathbf{x}f(t)dt, \tag{22}$$

and the apparent diffusion coefficient (ADC) accounts for the quadratic term in  $\gamma\tilde{\mathbf{g}}$ :

$$ADC_{new} = \frac{1}{|\Omega| \int_0^{TE} F(t)^2 dt} (A_1 + A_2 + A_3), \tag{23}$$

where the three terms that contribute to the ADC are:

$$A_1 = \int_0^{TE} \left( F(t)^2 \int_{\Omega} \mathbf{K}(t, \mathbf{x})\mathbf{u}_g \cdot \mathbf{u}_g \right) dt, \tag{24}$$

$$A_2 = - \int_0^{TE} \left( F(t) \int_{\Omega} (\mathbf{K}(t, \mathbf{x})\mathbf{u}_g \cdot \nabla\omega(\mathbf{x}, t)) \right) dt, \tag{25}$$

$$A_3 = - \int_0^{TE} \left( f(t) \int_{\Omega} \mathbf{u}_g \cdot \mathbf{d}(t, \mathbf{x})\omega(\mathbf{x}, t) \right) dt. \tag{26}$$

Using the divergence theorem for  $A_2$  and the definition of  $\tilde{\omega}$ , we get:

$$\begin{aligned} A_1 + A_2 = & - \int_0^{TE} \left( F(t) \int_{\partial\Omega} \tilde{\omega}(\mathbf{x}, t)\mathbf{K}(t, \mathbf{x})\mathbf{u}_g \cdot \mathbf{n}_x ds_x \right) dt \\ & + \int_0^{TE} \left( F(t) \int_{\Omega} \tilde{\omega}(\mathbf{x}, t)\text{div}(\mathbf{K}(t, \mathbf{x})\mathbf{u}_g) d\mathbf{x} \right) dt. \end{aligned}$$

Thus, we can split  $ADC_{new}$  into four terms as follows:

$$ADC_{new} = \frac{1}{|\Omega| \int_0^{TE} F(t)^2 dt} (A_a + A_b + A_c + A_d), \tag{27}$$

where

$$A_a = - \int_0^{TE} \left( F(t) \int_{\partial\Omega} \tilde{\omega}(\mathbf{x}, t)\mathbf{K}(t, \mathbf{x})\mathbf{u}_g \cdot \mathbf{n}_x ds_x \right) dt \tag{28}$$

$$A_b = - \int_0^{TE} \left( f(t) \int_{\Omega} \mathbf{u}_g \cdot \mathbf{d}(t, \mathbf{x})\tilde{\omega}(\mathbf{x}, t)d\mathbf{x} \right) dt \tag{29}$$

$$A_c = - \int_0^{TE} \left( f(t)F(t) \int_{\Omega} (\mathbf{u}_g \cdot \mathbf{d}(t, \mathbf{x}))(\mathbf{u}_g \cdot \mathbf{x})d\mathbf{x} \right) dt \tag{30}$$

$$A_d = \int_0^{TE} \left( F(t) \int_{\Omega} \tilde{\omega}(\mathbf{x}, t)\text{div}(\mathbf{K}(t, \mathbf{x})\mathbf{u}_g) d\mathbf{x} \right) dt. \tag{31}$$

### 4. Numerical results

In this section we validate the second order model (21) by comparing it against the reference signal in (6) from the BTPDE-D model.

#### 4.1. Deformation field

We design a homogeneous deformation field  $\varphi$  for heart cells (myocytes) given by:

$$\varphi(\mathbf{x}, t) = P(t)\mathbf{x}; \quad P(t) = \begin{pmatrix} P_{11}(t) & 0 & 0 \\ 0 & P_{22}(t) & 0 \\ 0 & 0 & P_{33}(t) \end{pmatrix} \tag{32}$$

with

$$P_{11}(t) = P_{22}(t) = 1 - V(t), \tag{33}$$

$$P_{33}(t) = 1 + Wk(t), \tag{34}$$

Fig. 1. The finite element-meshes of three cylinders that model a myocyte. The finite-element mesh of the straight cylinder has 13518 nodes and 54921 elements. The finite-element mesh of the twisted cylinder has 13515 nodes and 54883 elements, the bend cylinder has 13530 nodes and 55004 elements.

and

$$k(t) = \{ 0.5(1 - \cos(\pi t/T_s)) \text{if } t \leq T_s, 0.5(1 - \cos(\pi(t-T)/T_d)) \text{else.}$$

The parameter  $W \geq 0$  controls the amplitude of the deformation,  $T = 1000$  ms is the duration of one cardiac cycle, where  $T_s = T/3$  is the duration of the contraction of the heart (systolic phase) and  $T_d = 2T/3$  is the duration of dilation (diastolic phase). The function  $V(t)$  is taken in the form:

$$V(t) = 1 - \sqrt{1/P_{33}(t)}. \tag{35}$$

to ensure that

$$\det(P(t)) = 1, \forall t > 0.$$

The displacement field is thus:

$$\mathbf{d}(t, \mathbf{x}) = Q(t)\mathbf{x}, \quad Q(t) = \begin{pmatrix} P_{11}(t) - 1 & 0 & 0 \\ 0 & P_{22}(t) - 1 & 0 \\ 0 & 0 & P_{33}(t) - 1 \end{pmatrix},$$

and the Jacobian matrices, which are independent of  $\mathbf{x}$ , are:

$$\mathbf{J}_\phi(t) = P(t), \quad \mathbf{J}_d(t) = Q(t).$$

For this example, the diffusion tensor in the Bloch-Torrey PDE is given by:

$$\mathbf{K}(t) = \sigma(P^{-1}(t))^2.$$

The imaginary part of the signal is

$$S_{new}^{imag} = -\mathbf{u}_g^T \left( \int_0^{TE} Q(t)f(t)dt \right) \left( \frac{1}{|\Omega|} \int_\Omega \mathbf{x}d\mathbf{x} \right), \tag{36}$$

where  $\frac{1}{|\Omega|} \int_\Omega \mathbf{x}d\mathbf{x}$  is the center of mass of the domain. The first term in the ADC is

$$A_a = -\mathbf{u}_g^T \int_0^{TE} F(t)\sigma(Id + Q(t))^{-2} \left( \int_{\partial\Omega} \tilde{\omega}(\mathbf{x}, t)\mathbf{n}_x ds_x \right) dt, \tag{37}$$

where  $\int_{\partial\Omega} \tilde{\omega}(\mathbf{x}, t)\mathbf{n}_x ds_x$  describes the flux of  $\tilde{\omega}(\mathbf{x}, t)$  around the boundary. The second term of the ADC is

$$A_b = -\mathbf{u}_g^T \int_0^{TE} f(t)Q(t) \left( \int_\Omega \mathbf{x} \tilde{\omega}(\mathbf{x}, t) d\mathbf{x} \right) dt, \tag{38}$$

where  $\int_\Omega \mathbf{x} \tilde{\omega}(\mathbf{x}, t) d\mathbf{x}$  are the moments of  $\tilde{\omega}(\mathbf{x}, t)$  around the principle axes. Finally,

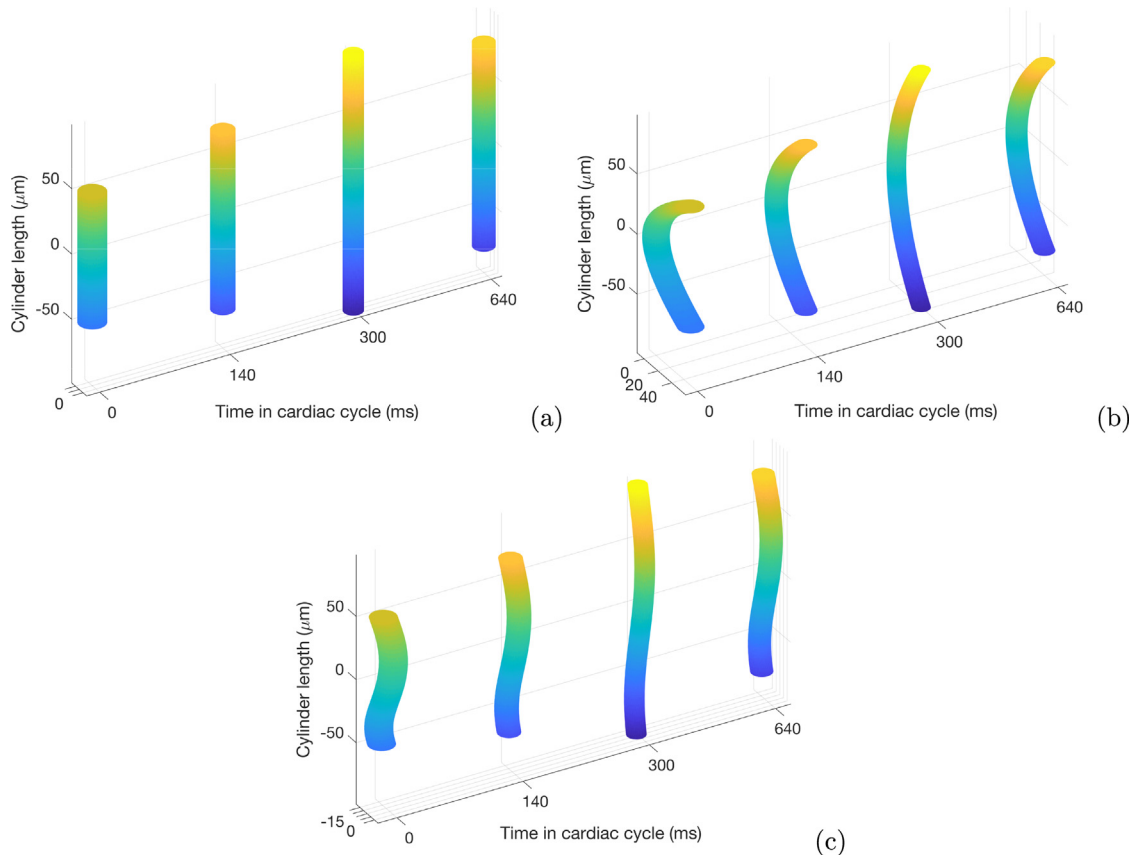

$$A_c = -\mathbf{u}_g^T \left( \int_0^{TE} f(t)F(t)Q(t)dt \right) \left( \int_\Omega \mathbf{x}\mathbf{x}^T d\mathbf{x} \right) \mathbf{u}_g, \tag{39}$$

where  $\int_\Omega \mathbf{x}\mathbf{x}^T d\mathbf{x}$  are the second order moments of the domain. The last term is independent of the space variable, i.e.:

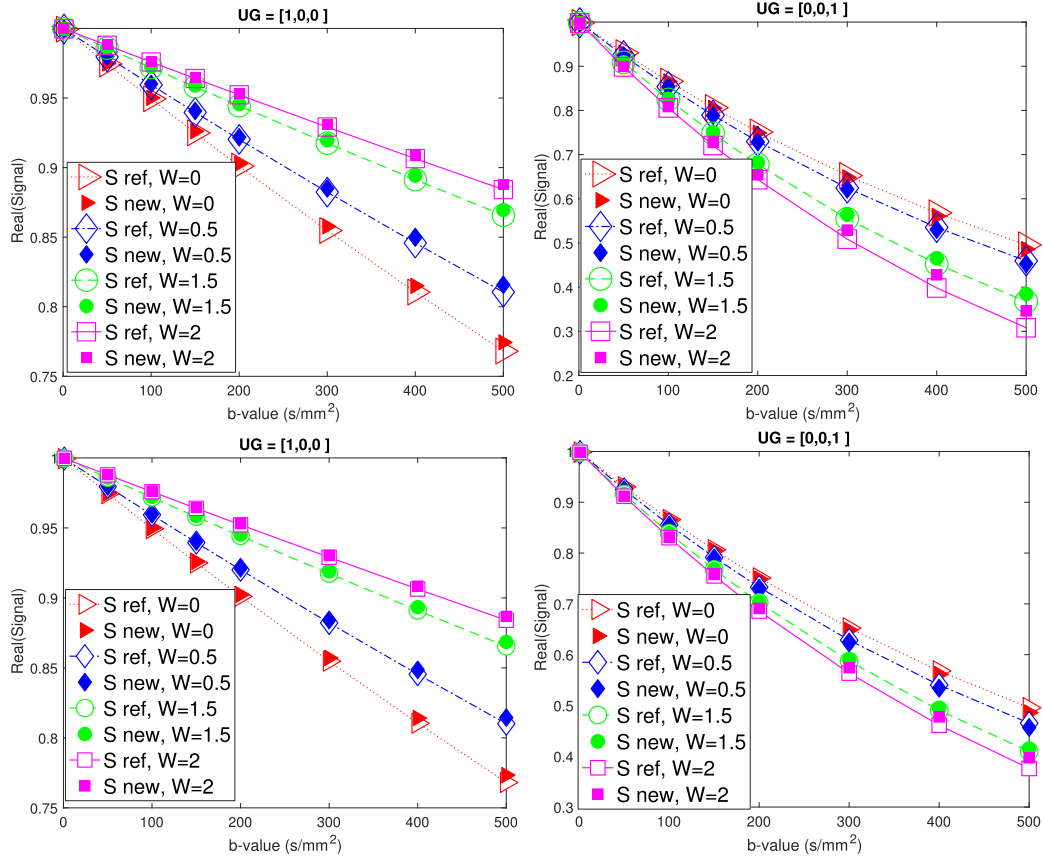

$$A_d = 0.$$

To study the effects of the geometry we consider a straight cylinder as the canonical geometry of the heart cell as well as two other geometries where the cylinder is twisted and bent, see Fig. 1.

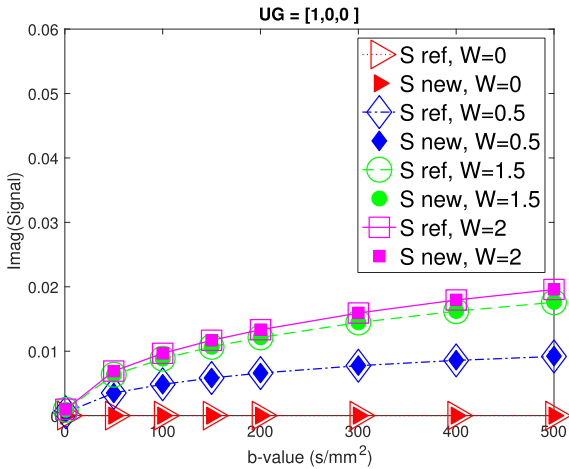

The values of  $W$  in the numerical simulations range between 0 and 2. The rate of the deformation is the same in the  $x$  and  $y$  directions. It is a contraction in the first third of  $[0, T]$  (systolic phase) and an extension in the remaining two-thirds (diastolic phase). In the  $z$ -direction, the first third of  $[0, T]$  is an extension and the remaining two-thirds is a contraction. There is no net motion between the starting and ending points of the diffusion MRI exper-

**Fig. 2.** Cylinders at different moments in cardiac deformation. From left to right:  $t = 0$  ms,  $t = 140$  ms (mid-systole),  $t = 300$  ms (end-systole),  $t = 640$  ms (mid-diastole). Deformation amplitude  $W = 1$ . Geometry: (a) Straight cylinder. (b) Bent cylinder. (c) Twisted cylinder.

**Fig. 3.** Real part of the reference signal and the new second order approximation signal as a function of b-value for different values of  $W$ , the deformation parameter ( $W = 0$  means the cell is static during the diffusion MRI sequence). Sequence parameters:  $\delta = 5$  ms and  $\Delta = 40$  ms. Top left:  $t = 140$  ms (mid-systole),  $\mathbf{u}_g = (1, 0, 0)$ . Top right:  $t = 140$  ms (mid-systole),  $\mathbf{u}_g = (0, 0, 1)$ . Bottom left:  $t = 640$  ms (mid-diastole),  $\mathbf{u}_g = (1, 0, 0)$ . Bottom right:  $t = 640$  ms (mid-diastole),  $\mathbf{u}_g = (0, 0, 1)$ . Geometry: straight cylinder. Deformation field: Homogeneous (Eqs. (32)–(35)).

**Fig. 4.** Imaginary part of the reference signal and the new second order approximation signal as a function of b-value for different values of the deformation parameter  $W$  ( $W = 0$  means the cell is static during the diffusion MRI sequence),  $t = 140$  ms (mid-systole) of the cardiac cycle. Sequence parameters:  $\delta = 5$  ms and  $\Delta = 40$  ms. Geometry: straight cylinder. Deformation field: Homogeneous (Eqs. (32)–(35)).

iment over the interval  $[0, T]$ . The effect of the deformation is presented in Fig. 2 for the straight, bent and twisted cylinders at different times in the cardiac cycle.

We will also simulate a space-dependent deformation field, given by the following equations:

$$P_{33}(t, z) = 1 + Wz^2k(t), \quad (40)$$

$$V(t) = 1 - \sqrt{1/P_{33}(t, z)} \approx \frac{1}{2}Wz^2k(t), \quad (41)$$

$$P_{11}(t, z) = P_{22}(t, z) = 1 - V(t, z), \quad (42)$$

$$\approx 1 - \frac{1}{2}Wz^2k(t).$$

The deformation  $\varphi$  defined as:

$$\varphi(t, \mathbf{x}) = P(t, z)\mathbf{x}$$

with

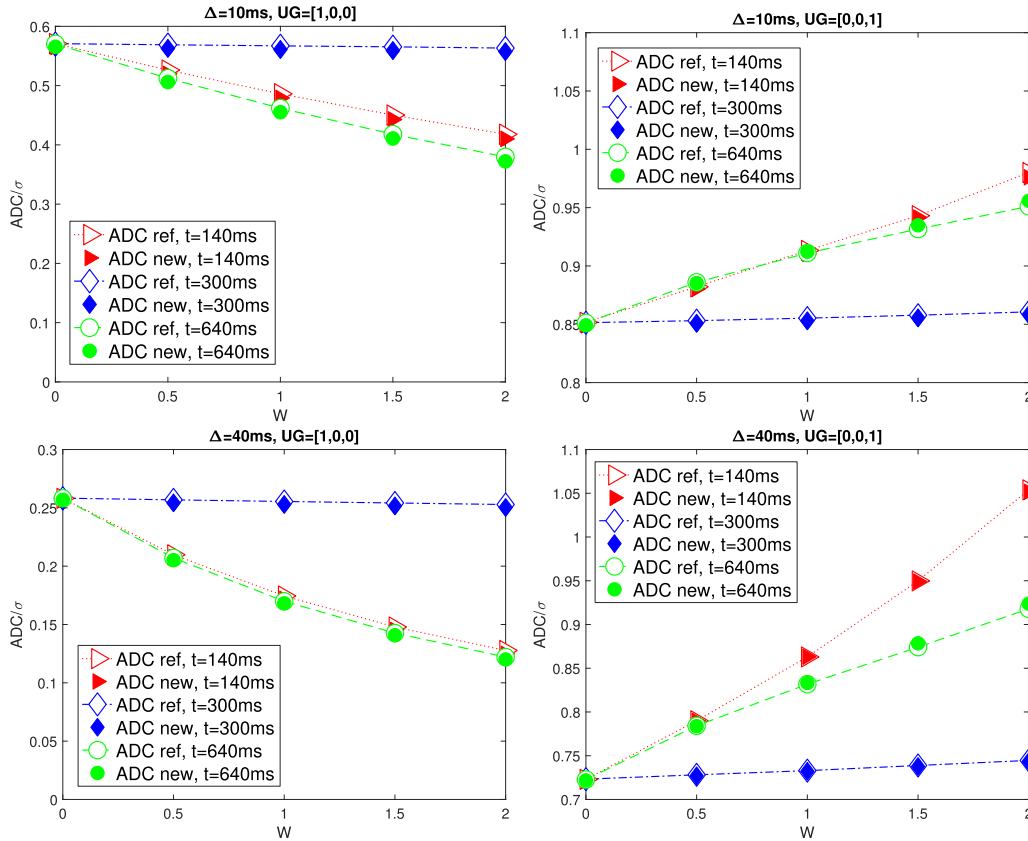

$$P(t, z) = \begin{pmatrix} P_{11}(t, z) & 0 & 0 \\ 0 & P_{22}(t, z) & 0 \\ 0 & 0 & P_{33}(t, z) \end{pmatrix}$$

will be written as:

$$\varphi(\mathbf{x}, t) = \begin{pmatrix} \left(1 - \frac{1}{2}Wz^2k(t)\right)x \\ \left(1 - \frac{1}{2}Wz^2k(t)\right)y \\ \left(1 + Wz^2k(t)\right)z \end{pmatrix}. \quad (43)$$

#### 4.2. Simulations for one cylindrical cell

In this section we numerically compare the reference signal  $S_{ref}$  in Eq. (6) and the newly derived signal  $S_{new}$  in Eq. (21). We solve (5)

**Fig. 5.** The normalized ADC of the reference signal and the ADC of the new second order approximation signal as function of the deformation parameter  $W$  ( $W = 0$  means the cell is static during the diffusion MRI sequence), at different time points in the cardiac cycle:  $t = 140, 300, 640$  ms. Top left, PGSE ( $\delta = 5$  ms,  $\Delta = 10$  ms),  $\mathbf{u}_g = (1, 0, 0)$ . Top right, PGSE ( $\delta = 5$  ms,  $\Delta = 10$  ms),  $\mathbf{u}_g = (0, 0, 1)$ . Bottom left, PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms),  $\mathbf{u}_g = (1, 0, 0)$ . Bottom right, PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms),  $\mathbf{u}_g = (0, 0, 1)$ . Geometry: straight cylinder. Deformation field: Homogeneous (Eqs. (32)–(35)).

to obtain the reference signal and we solve (16) to obtain the new signal. The numerical implementation was done in Matlab using P1 finite elements for the space discretization coupled to the ODE solver "ode23t" for the time integration. The equations were solved on a cylinder of radius  $10 \mu\text{m}$  and height  $100 \mu\text{m}$ .

We chose the PGSE sequence [17] with pulse duration  $\delta = 5$  ms and two values of the diffusion time:  $\Delta = 10$  ms and  $\Delta = 40$  ms. The intrinsic diffusion coefficient is chosen as  $\sigma = 2 \times 10^{-3} \text{ mm}^2/\text{s}$ , and the initial condition  $\rho \equiv 1$  T.

For the simulations presented in Figs. 3–7, we used the homogeneous deformation field (Eqs. (32)–(35)).

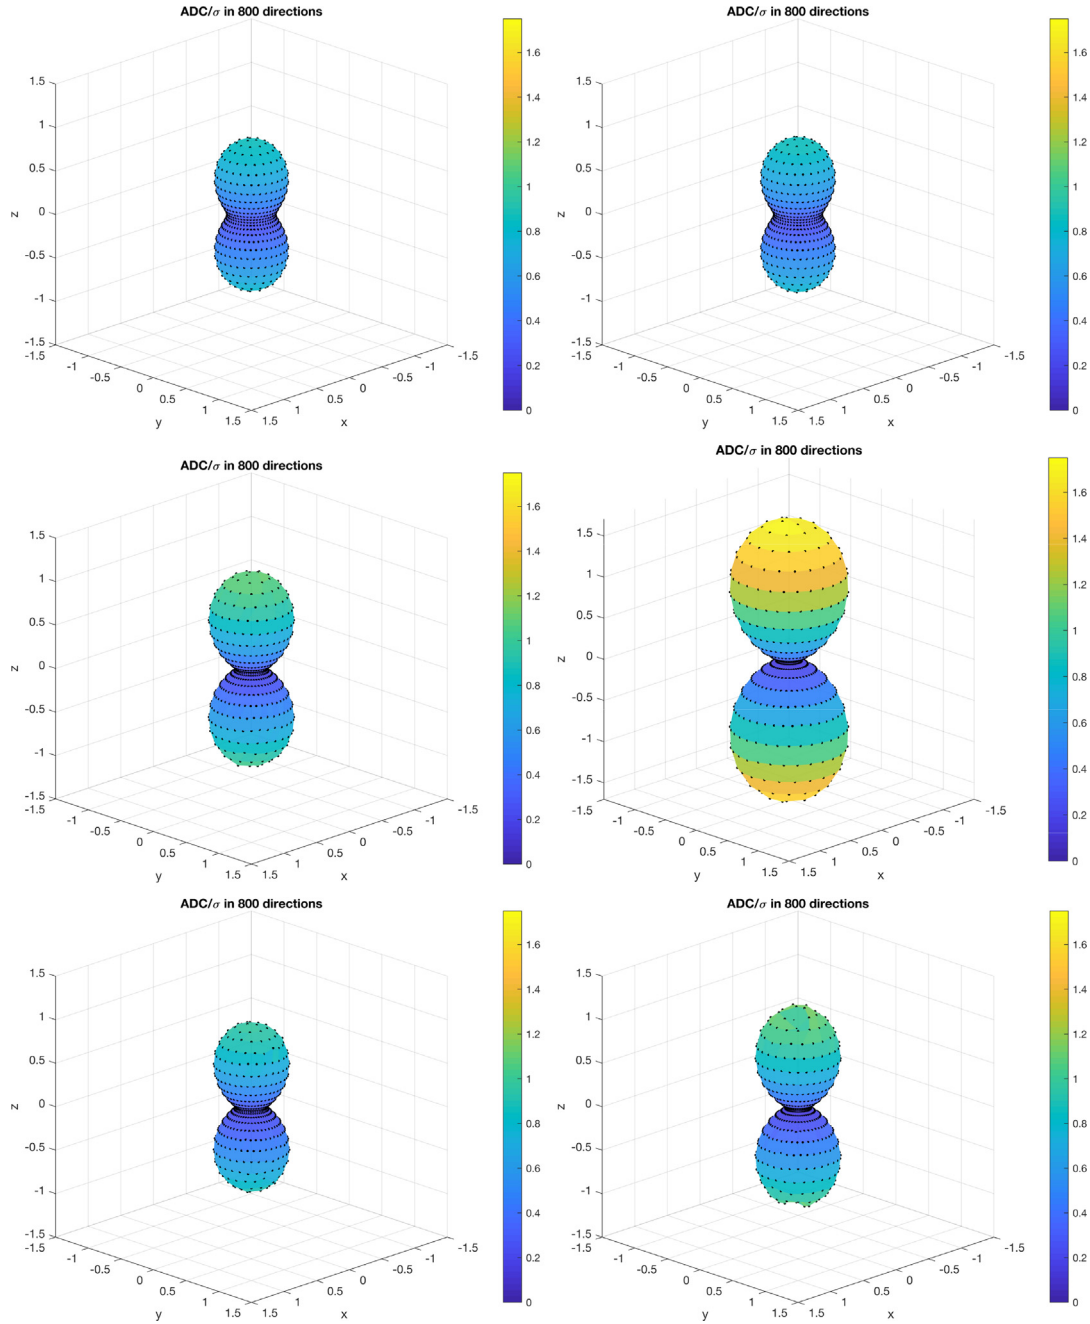

In Fig. 3 we show the real part of the diffusion MRI signal for  $S_{ref}$  (6) and  $S_{new}$  (21) for two diffusion-encoding directions:  $\mathbf{u}_g = (1, 0, 0)$  and  $\mathbf{u}_g = (0, 0, 1)$ , with  $\delta = 5$  ms and  $\Delta = 40$  ms. We compute the signal during a diffusion sequence at two different points of the cardiac cycle:  $[t, t + TE]$ ,  $t = 140$  ms (mid-systole) and  $t = 640$  ms (mid-diastole). For diffusion in the  $x$ -direction, we observe that the new second order approximation signal is close to the reference signal for all deformation parameter  $W$ , for  $b$ -values up to  $500 \text{ s}/\text{mm}^2$ , at both time points of the cardiac cycle. However, in the diffusion direction  $z$ ,  $\mathbf{u}_g = (0, 0, 1)$ , the new second order approximation signal is less close to the reference signal for large values of  $W$ , and the inaccuracy is more significant at higher  $b$ -values (higher  $g$ ). This is a consequence of our design of the deformation to be more significant in the  $z$ -direction than in the  $x$  and  $y$  directions.

In Fig. 4 we show the imaginary part of the new second order approximation signal,  $S_{new}^{imag}$ , for diffusion encoding in the  $x$ -direction,  $\mathbf{u}_g = (1, 0, 0)$ , at  $t = 140$  ms (mid-systole) in the cardiac

cycle. Due to the presence of cardiac deformation ( $W \neq 0$ ), the imaginary part of the signal is non-zero, unlike the case without deformation ( $W = 0$ ).

Next, we compare the reference  $ADC_{ref}$  (3) and the newly derived  $ADC_{new}$  (27), both normalized by dividing by the intrinsic diffusion coefficient  $\sigma$ . In Fig. 5, we show the normalized ADCs in two diffusion-encoding directions:  $\mathbf{u}_g = (1, 0, 0)$  and  $\mathbf{u}_g = (0, 0, 1)$ , at several different time points in the cardiac cycle:  $t = \{140, 300, 640\}$  ms, for two diffusion-encoding sequences: PGSE ( $\delta = 5$  ms,  $\Delta = 10$  ms) and PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms). It can be seen that the ADC of the new second order approximation signal model is very accurate for describing the ADC of the reference model.

In Fig. 6, we show the normalized ADC of the new second order approximation signal model (27), computed in 800 directions, uniformly distributed in the unit sphere, for the sequence PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms). The results are presented for the deformation amplitude  $W = 0$  (without deformation effect) and  $W = 1, W = 2$ . The ADC is computed for different time points in the cardiac cycle:  $t = \{140, 300, 640\}$  ms. As in Fig. 5 we see that the ADC without cardiac deformation ( $W = 0$ ) coincides with the one at the end of the systolic phase ( $t = 300$  ms) because in that moment the time variation of the heart deformation is negligible. This confirms the simulation results obtained in [35] and the experimental results in [10]. To show the effect of the deformation amplitude  $W$ , we compare the ADC at  $t = 140$  ms and  $t = 640$  ms of the cardiac cycle for  $W = 1$  and  $W = 2$ . We see clearly that the larger  $W$  induces a larger ADC in the  $z$  direction. This effect is minimal in the  $x$  and  $y$  diffusion-encoding directions.

**Fig. 6.** Normalized ADC of the new second order approximation signal model (27), computed in 800 directions, uniformly distributed in the unit sphere, for the sequence PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms),  $W$  is the deformation parameter,  $t$  indicates the point in the cardiac cycle. Top left:  $W = 0$  (no deformation). Top right:  $W = 1$ ,  $t = 300$  ms. Middle left:  $W = 1$ ,  $t = 140$  ms. Middle right:  $W = 2$ ,  $t = 140$  ms. Bottom left:  $W = 1$ ,  $t = 640$  ms. Bottom right:  $W = 2$ ,  $t = 640$  ms. The black points are the magnitude of the normalized ADC multiplied by the diffusion-encoding direction. The color indicates the value of the normalized ADC. Geometry: straight cylinder. Deformation field: Homogeneous (Eqs. (32)–(35)).

In Fig. 7 we show the effect of the shape of the cylindrical cell on the ADC. We compute the normalized ADC of the new second order approximation signal model (27), in 800 directions, uniformly distributed on the unit sphere, for the sequence PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms) for the bent cylinder (Fig. 2)) and the twisted cylinder (Fig. 2(c)). Again, we observe that the ADC without cardiac deformation ( $W = 0$ ) coincides with the one at the end systolic phase ( $t = 300$  ms) when the variation of the heart deformation during the application of the diffusion encoding sequence is negligible.

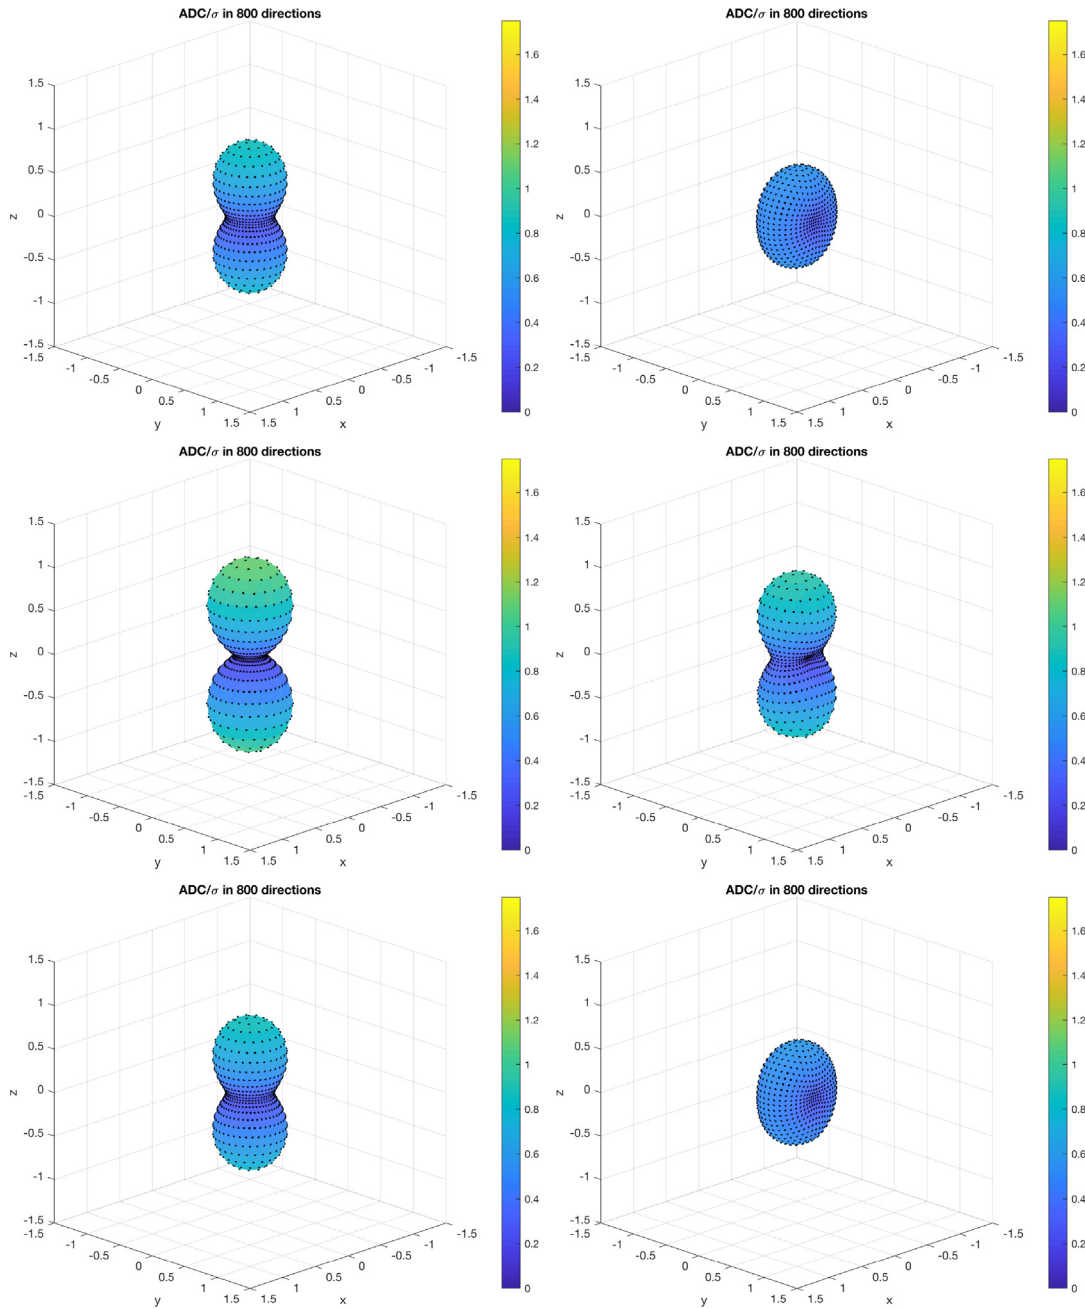

We see that the ADC for the twisted cylinder and the straight cylinder are similar, whereas the ADC of the bent cylinder is

significantly different. To explain this phenomenon, we show the differences in the directional surface to volume ratios of these 3 geometries. The directional surface to volume ratio comes up in the well-known formula for the ADC in the short diffusion time regime. The short time approximation (STA) [36,37] formula is the following (with correction for non-narrow pulses [38]):

$$STA = \sigma \left[ 1 - \frac{4\sqrt{\sigma}}{3\sqrt{\pi}} C_{\delta,\Delta} \frac{A_{\mathbf{u}_g}}{V} \right], \quad (44)$$

with  $\sigma$  being the intrinsic diffusivity coefficient, and

**Fig. 7.** Normalized ADC of the new second order approximation signal model (27), computed in 800 directions, uniformly distributed in the unit sphere, for the sequence PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms). The black points are the magnitude of the normalized ADC multiplied by the diffusion-encoding direction. The color indicates the value of the normalized ADC.  $W$  is the deformation parameter,  $t$  indicates the point in the cardiac cycle. Top left: twisted cylinder,  $W = 0$  (no deformation effect). Top right: bend cylinder,  $W = 0$  (no deformation effect). Middle left: twisted cylinder,  $W = 1$  and  $t = 140$  ms. Middle right: bend cylinder,  $W = 1$  and  $t = 140$  ms. Bottom left: twisted cylinder,  $W = 1$  and  $t = 300$  ms. Bottom right: bend cylinder,  $W = 1$  and  $t = 300$  ms. Deformation field: Homogeneous (Eqs. (32)–(35)).

$$A_{\mathbf{u}_g} = \int_{\partial\Omega} (\mathbf{u}_g \cdot \mathbf{n})^2 ds$$

is the gradient direction dependent surface area, the pulse separation and pulse duration are accounted for by:

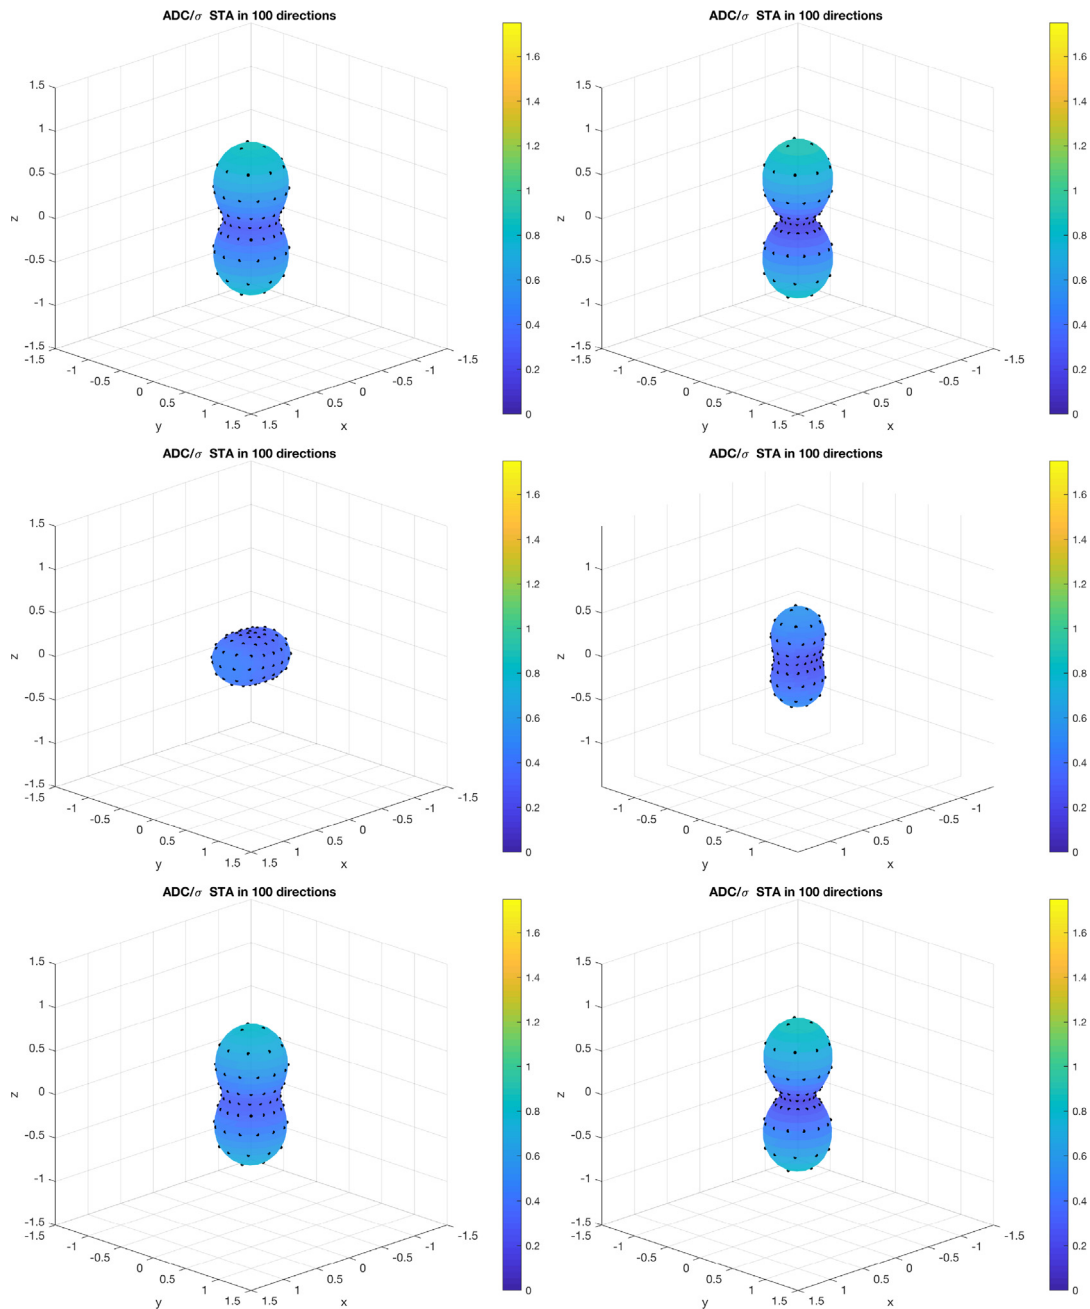

$$C_{\delta,\Delta} = \frac{4}{35} \frac{(\Delta + \delta)^{7/2} + (\Delta - \delta)^{7/2} - 2(\delta^{7/2} + \Delta^{7/2})}{\delta^2(\Delta - \delta/3)}$$

$$= \sqrt{\Delta} \left( 1 + \frac{1}{3} \frac{\delta}{\Delta} - \frac{8}{35} \left( \frac{\delta}{\Delta} \right)^{3/2} + \dots \right).$$

When  $\delta \ll \Delta$ , the value  $C_{\delta,\Delta}$  is approximately  $\sqrt{\Delta}$ .

In Fig. 8, we show the ADC obtained by evaluating the above STA formula. It is clear that the STA formula closely tracks the shapes of the ADC shown in Figs. 6 and 7. There is a minor difference in the case of the bend cylinder when  $W = 0$  (the sphere being flat along the  $z$ -axis rather than the  $y$ -axis), but clearly, the directional surface area of the bend cylinder is significantly different than those of the straight and twist cylinders.

Now we show simulation results of the non-homogeneous deformation field (Eqs. (40)–(43)). In Fig. 9, we can see that, similar to the homogeneous deformation field we showed previously, the higher signal curves in the  $x$ -direction are due to a more deformed field (higher  $W$ ), and in the  $z$ -direction, they are due to a less

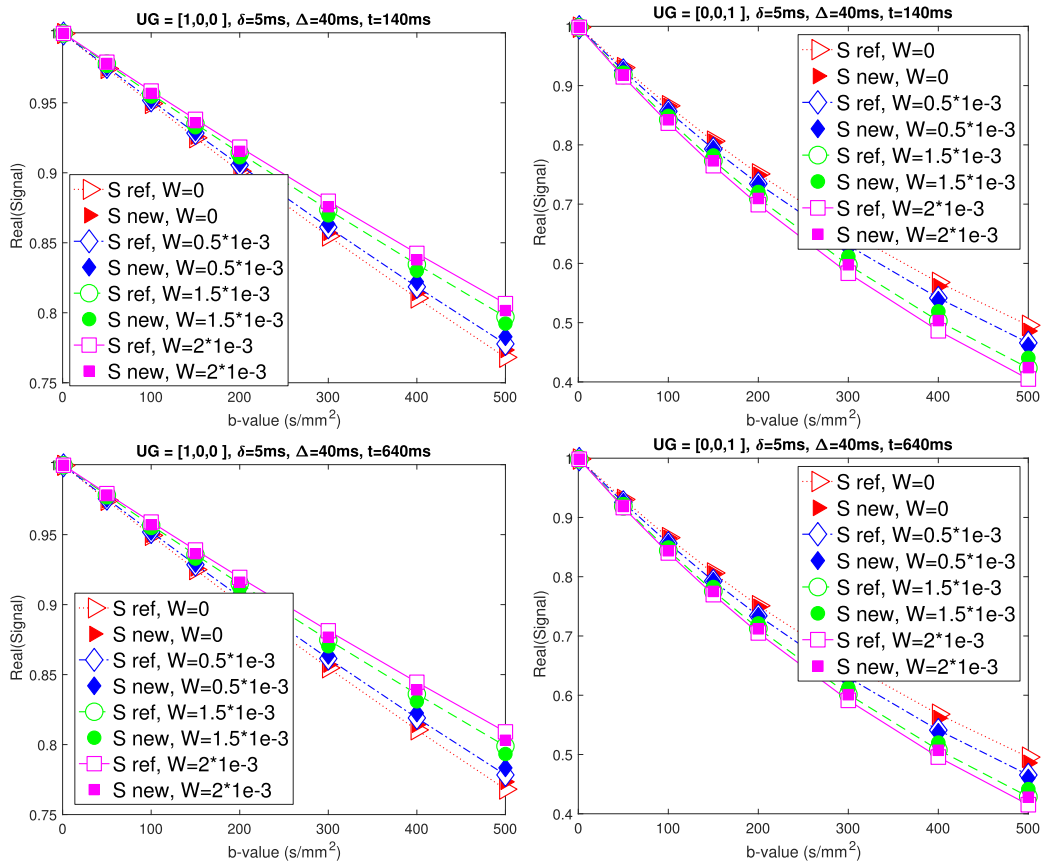

**Fig. 8.** Normalized ADC in the short time approximation regime (STA), computed in 100 directions, uniformly distributed in the unit sphere, for the sequence PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms). The black points are the magnitude of the normalized ADC multiplied by the diffusion-encoding direction. The color indicates the value of the normalized ADC.  $W$  is the deformation parameter,  $t$  indicates the point in the cardiac cycle. Top left: straight cylinder,  $W = 0$  (no deformation effect). Top right: straight cylinder,  $W = 1$ ,  $t = 140$  ms. Middle left: bend cylinder,  $W = 0$ . Middle right: bend cylinder,  $W = 1$ ,  $t = 140$  ms. Bottom left: twisted cylinder,  $W = 0$ . Bottom right: twisted cylinder,  $W = 1$ ,  $t = 140$  ms. Deformation field: Homogeneous (Eqs. (32)–(35)).

deformed field (lower  $W$ ). Also similar to the homogeneous deformation field, the ADC in Fig. 10 at time  $t = 300$  ms for non-zero values of  $W$  is approximately the same as for  $W = 0$ . However, some differences can be seen between the two deformation fields. For example, in the  $z$ -direction, the differences at larger  $W$  between the ADC at  $t = 140$  ms and the ADC at  $t = 640$  ms are smaller for the non-homogeneous deformation field than for the homogeneous one. This difference can be seen also in Fig. 11, where we show the magnetization solution at TE for the straight cylinder undergoing the two deformations. For the homogeneous deformation field, the difference in the magnetization solution between  $t = 140$  ms and  $t = 640$  ms are more significant than for the case of the non-homogeneous deformation field.

### 4.3. Computational time

In Table 1 we show the computational times for the simulation of the reference model (BTPDE-D) and the new second order approximation model for the straight cylinder. All the simulations were performed on a server computer with 12 processors (Intel (R) Xeon (R) E5-2667 @2.90 GHz), 192 GB of RAM, running CentOS 7, using MATLAB R2019a. It can be seen that the new second order model takes about 70% of the computational time of the reference model. In Table 2 we show the computational times to simulate the new second order model for the twisted and bend cylinders. The computational times do not depend on the value of the deformation parameter  $W$  and on the point of the cardiac cycle simulated.

**Fig. 9.** Real part of the reference signal and the new second order approximation signal as a function of b-value for different values of W, the deformation parameter ( $W = 0$  means the cell is static during the diffusion MRI sequence). Sequence parameters:  $\delta = 5$  ms and  $\Delta = 40$  ms. Top left:  $t = 140$  ms (mid-systole),  $\mathbf{u}_g = (0, 0, 1)$ . Top right:  $t = 640$  ms (mid-diastole),  $\mathbf{u}_g = (1, 0, 0)$ . Bottom left:  $t = 640$  ms (mid-diastole),  $\mathbf{u}_g = (0, 0, 1)$ . Bottom right:  $t = 140$  ms (mid-systole),  $\mathbf{u}_g = (1, 0, 0)$ . Geometry: straight cylinder. Deformation field: Non-homogeneous (Eqs. (40)–(43)).

**Fig. 10.** The normalized ADC of the reference signal and the ADC of the new second order approximation signal as function of the deformation parameter  $W$  ( $W = 0$  means the cell is static during the diffusion MRI sequence), at different time points in the cardiac cycle:  $t = 140, 300, 640$  ms. Left, PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms),  $\mathbf{u}_g = (1, 0, 0)$ . Right, PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms),  $\mathbf{u}_g = (0, 0, 1)$ . Geometry: straight cylinder. Deformation field: Non-homogeneous (Eqs. (40)–(43)).

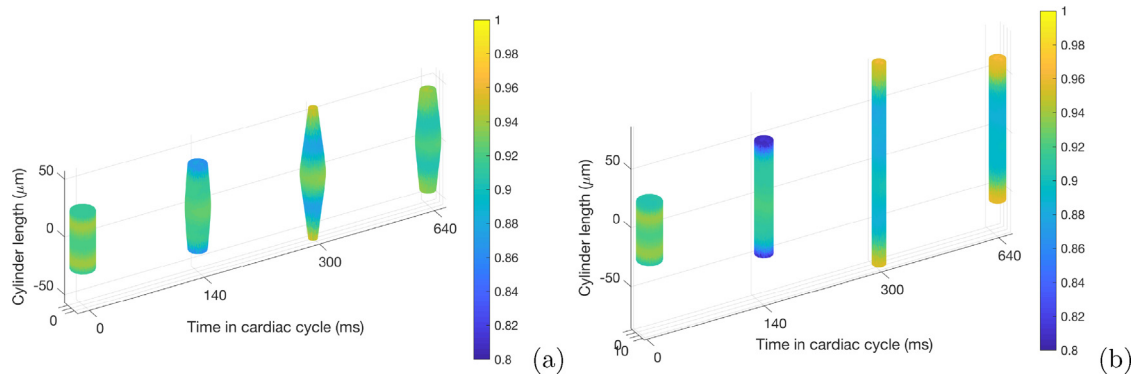

These computational times are provided to illustrate typical simulation times. Though the advantages of the new second order model include shorter simulation times, more significant advantages lie in the fact that it is more amenable to mathematical analysis.

### 5. Concluding remarks

We derived a second order (in the diffusion-encoding gradient magnitude  $g$ ) signal perturbation model whose linear term gives

the imaginary part of the diffusion MRI signal and whose quadratic term gives the ADC attributable to the biological cell. We numerically validated this model for a constructed example of cardiac motion and deformation using a finite element discretization of the equations in a cylindrical cell.

This work is a first step to understand the origins of the imaginary part of the diffusion MRI signal in the case of moving and deforming domains and the deviation of the ADC from that which is measured in the case of a static domain. By formulating the second order model, we are able to write the different contributing

**Fig. 11.** Magnetization solution of Eq. (5) at echo time (TE) for  $\delta = 5$  ms,  $\Delta = 40$  ms,  $\mathbf{u}_g = (0, 0, 1)$  and  $b$ -value =  $50$  s/mm<sup>2</sup>. Moments of the cardiac cycle: From left to right:  $t = 0$  ms,  $t = 140$  ms (mid-systole),  $t = 300$  ms (end-systole),  $t = 640$  ms (mid-diastole). Geometry: straight cylinder. (a) Non-homogeneous deformation field (Eqs. (40)–(43)). Deformation amplitude  $W = 2 \times 10^{-3}$ . (b) Homogeneous deformation field (Eqs. (32)–(35)). Deformation amplitude  $W = 2$ .

**Table 1**

The average computational times to obtain the ADC, per diffusion-encoding direction. Geometry: straight cylinder (13518 nodes and 54921 elements).

	Reference model (BTPDE-D)	New 2nd order model
$\delta = 5$ ms, $\Delta = 10$ ms	71.62 s	47.99 s
$\delta = 5$ ms, $\Delta = 40$ ms	72.53 s	51.04 s

**Table 2**

The computational times to obtain the new 2nd order model, per diffusion-encoding direction. The sequence is PGSE ( $\delta = 5$  ms,  $\Delta = 40$  ms).

Finite-element mesh size	New 2nd order model

Bend cylinder Nodes: 13530, Elements: 55004	55.1 s

factors to the linear and the quadratic terms in (21). In particular, we related the imaginary part of the signal to the center of mass of the domain (22) and the ADC to four contributing terms (27). We gave a physical interpretation to these contributing factors in terms of the flux and the moments of the function  $\tilde{\omega}(\mathbf{x}, t)$ . The next step is to understand  $\tilde{\omega}(\mathbf{x}, t)$ , which is a solution of a diffusive PDE subject to zero initial conditions and homogeneous Neumann boundary conditions.

In addition to providing an analytic understanding of the diffusion MRI of moving and deforming domains, our work also included the implementation of a numerical method to simulate the BTPDE-D model and the new second order approximation signal model.
